Abstract. North Cascade glacier annual balance measured on 10 glaciers from 1984–2006 yielded mean annual balance (b_a) of -0.54 m/a, and -12.38 m cumulatively. This is a significant loss for glaciers that average 30–60 m in thickness, 20–40% of their entire volume. Two observed glaciers, Lewis Glacier and Spider Glacier, no longer exist.

The b_a of North Cascade glaciers is reliably calculated, correlation coefficient 0.91, using 1 April snowpack water equivalent and ablation season temperature. Utilizing b_a from 10 glaciers 1984–2006 and net balance (b_n) from South Cascade 1960–2005, a set of forecast rules for glacier mass balance were derived utilizing October–April Pacific Decadal Oscillation and Multivariate El Niño Southern Oscillation index values. The forecast rules provide a correct assessment in 41 of the 46 years for South Cascade Glacier and 20 of 23 years for NCGCP glaciers. Glacier annual balance forecasting is an important step for summer water resource management in glacier runoff dominated stream systems. The forecast for North Cascade glaciers in 2007 is for a negative b_a .

North Cascade glaciers from atmospheric circulation indices of the Pacific Basin? This paper is the first step in approaching the problem of glacier mass balance forecasting. Many papers have focused on modelling glacier mass balance from climate records, but this has limited utility for water resource management purposes, as the calculation postdates the hydrologic year.

The North Cascade region contains more than 700 glaciers, which cover 250 km^2 and range in elevation from 1500–2500 m (Post et al., 1971). During the 1984–2006 period all 47 observed glaciers have been retreating (Peltó, 2006). The importance of monitoring glacier mass balance was recognized during the International Geophysical Year in 1957. A series of benchmark glaciers around the world were chosen where mass balance would be monitored. This network has proven valuable, although coverage within any region is sparse. For example, there is just one benchmark glacier (South Cascade Glacier) in the lower 48 United States with ongoing measurements. Regional variation in glacier mass balance is due to variation in geographic characteristics such as aspect, elevation and location with respect to prevailing winds. No single glacier is representative of all others. Therefore, to understand the causes and nature of changes in glacier surface mass balance throughout a mountain range, it is necessary to monitor a significant number of glaciers (Fountain et al., 1991). The North Cascade Glacier Climate Project (NCGCP) was founded in 1983 to monitor glaciers throughout the range and identify the response of North Cascade Range, Washington glaciers to regional climate change. In 1983 the NCGCP selected for a long term annual balance monitoring 10 glaciers representing each part of the range and each type of glacier (Peltó, 1988). The glaciers represent a range of geographic conditions (Table 1). Annual balance has been continued on the 8 original glaciers that still exist, two have disappeared, Lewis and Spider Glacier, the latter on the north flank of Chiwawa Peak. No relict glacier ice

1 Introduction

Glaciers have been studied as sensitive indicators of climate for more than a century. Glacier behavior integrates water and energy balance factors to exhibit a maximum climate change signaling effect (IPCC, 1996). The North Cascades climate is known to be sensitive to inter-annual and decadal fluctuations in Pacific Basin climate (Walters and Meier, 1989; Hodge et al., 1998; Peltó and Hedlund, 2001; Bitz and Battisti, 1999). How reliably do North Cascade glaciers record climate? Can we forecast annual balance of

remains in the Lewis Glacier basin, and the largest relict ice is 0.006 km² for Spider Glacier. In 1990, Easton Glacier and Sholes Glacier were added to the annual balance program to offset the loss.

This paper focuses on data from this twenty-three year mass balance program and a 47 year record from the regional benchmark glacier, South Cascade Glacier monitored by the USGS (Krimmel, 2000; Bidlake et al., 2007).

2 Methods

Annual mass balance measurements are the most sensitive indicator of short-term glacier response to climate change. Annual mass balance is the difference between accumulation of snow and ice in winter and loss of snow and ice by ablation in summer. It is typically measured on a fixed date near the end of the water year, beginning 1 October and ending 30 September.

NCGCP methods emphasize surface mass balance measurements with a relatively high density of sites on each glacier (>100 sites/km²), consistent measurement methods, applied on fixed dates, and at fixed measurement locations (Peltó, 1996; Peltó and Riedel, 2001). Glaciers monitored in this program do not lose significant mass by calving or avalanching, thus changes observed are primarily a function of winter accumulation and summer ablation on the glacier's surface.

NCGCP essentially measures conditions on a glacier near the time of minimal mass balance at the end of the water year, using a fixed date method. This is known as annual balance (Mayo et al, 1972; Peltó, 1997). Measurements are made at the same time each year in July–August and again in late September near the end of the ablation season. Any additional ablation that occurs after the last visit to a glacier is measured during the subsequent hydrologic year. Annual balance can be determined with this approach because winter and summer balance quantities, not measured prior to the NCGCP field season, cancel each other (Peltó and Riedel, 2001). Net balance in contrast (b_n) is defined as the change observed on a glacier's surface between successive balance minimums (Mayo et al., 1972).

Detailed descriptions of NCGCP methods have been documented in (Peltó, 1996, 1997, 2000; Peltó and Riedel, 2001). The use of a high measurement density and consistent methods provides that errors resulting from an imperfectly

Fig. 2. The b_a of North Cascade glaciers and b_n for South Cascade glacier 1984–2006, records for individual glaciers are difficult to distinguish due to the consistently high correlation between glaciers.

representative measurement network are largely consistent and correctable (Peltó, 2000).

3 Results and discussion

The cumulative balance trend, for the 10 NCGCP glaciers indicate an increasing trend of negative mass balance. The trend has become more negative and the interannual variation has increased. The mean annual balance from 1984 to 2006 on North Cascade glaciers is -0.54 m/a (Table 2). The cumulative balance is -12.38 m, equal to an ice thickness loss of at least 14 m (Fig. 3). Given a mean thickness of 30–60 m the mass loss is a 20–40% loss in total glacier volume. The increase in negative balance during a period of substantial retreat, suggests that the current retreat is insufficient for the glaciers to approach equilibrium. Glacier retreat during a period of fixed climate would increase mass balance as a glacier approached equilibrium.

Cross correlation of annual balance and net balance data from NCGCP and USGS programs support the comparison of the two data sets. Correlation coefficients between glaciers using the different field methods range from $r^2=0.79$ to 0.92 (Table 3). South Cascade Glacier has the largest negative balance, and has had the most significant retreat of this group in the last 20 years. The extensive retreat further supports that its mass balance has been more negative. Annual data from the eleven glaciers demonstrate the high degree of correlation (Fig. 2; Table 3). The linear trends overlap consistently enough that picking out an individual glacier record is difficult in Fig. 2, indicating the similarity in sensitivity to annual climate conditions. There is a substantial annual range from maximum to minimum b_a values averaging 0.75 m, however the variation from year to year is remarkably similar for all glaciers. Some years peculiarities occur that alter the annual

Fig. 3. Cumulative mass balance record of North Cascade glaciers, 1984–2006, in meters of water equivalent. The increasingly negative trend is evident.

balance of a particular glacier. For example a huge avalanche descended onto the Columbia Glacier in 2002 resulting in the most positive b_a of any glacier. In 2003, snowpack depths were below normal on all glaciers except above 2200 m on Easton Glacier, and it had the least negative b_a .

The loss in volume represents an extensive thinning, which has led to significant retreat of each glacier. This resulted in the final loss of Spider and Lewis Glacier. The Foss Glacier and Ice Worm Glacier have lost more than 30% of their total area since 1984 changing their character substantially, neither glacier will persist long with the current climate.

4 Modeled versus measured annual balance

NCGCP has a temporally long enough glacier b_a record to be contrasted meaningfully with climate data and climate

indices. The two key climate variables are ablation season temperature and accumulation season precipitation (Fig. 4). We examined ablation season temperature for five regional weather stations and for two different month combinations (May–September and June–September) and found the Diablo Dam record for June–September provides the best correlation with b_a . For accumulation season precipitation, annual balance was correlated with precipitation at Diablo Dam and Concrete WA for differing combinations of

months, and with 1 April snow water equivalent (SWE) at five United States Department of Agriculture (USDA) Snowpack Telemetry stations (SNOTEL) stations; Rainy Pass, Lyman Lake, Stevens Pass, Miners Ridge and Fish Lake. The best correlation is with 1 April SWE. 1 April is near the snowpack maximum for most of the SNOTEL sites (Mote, 2003).

In Fig. 4, 1 April SWE has declined by 25% at these stations since 1946, while winter season precipitation

Fig. 4. 1 April SWE at five USDA Snotel stations and ablation season temperature (June–September) at Diablo Dam from 1946–2006. This illustrates the 0.6°C ablation season (June–September) warming and 25% decline in 1 April SWE.

Fig. 5. Scatter plot and linear regression of ablation season temperature (June–September) at Diablo Dam and measured annual balance of North Cascade glaciers for the 1984–2004 period.

Fig. 6. Scatter plot and linear regression line between mean 1 April SWE at five USDA SNOTEL stations and measured annual balance of North Cascade glaciers for the 1984–2004 period.

(November–March) has increased 1–3% at Concrete and at Diablo Dam, the most reliable long term weather stations. Mote (2003) in examining 40 stations in the Washington and British Columbia noted that substantial declines in SWE coincide with significant increases in winter temperature, and occur in spite of increases in winter precipitation.

In Figs. 5 and 6, b_a is plotted against ablation season temperature at Diablo Dam and 1 April SWE respectively. The resulting linear regression equations were then simply com-

bined to calculate annual balance. The resulting equation requires as input only the mean June–September temperature at Diablo Dam (T) and the mean 1 April SWE (s) at the SNOTEL stations. This calculation was also performed using multiple linear regression. The value of r between the calculated and measured b_a is 0.91 for multiple regression. Equation (1) is appropriate if the variables are independent.

$$b_a = 7.03048 - 0.614959T + 2.219146s \quad (1)$$

Fig. 7. Scatter plot of calculated versus measured annual balance on North Cascade glaciers 1984–2006. Annual Balance calculated using multiple regression from Eq. (1) with 1 April SWE and June–September T.

Figure 7 has the calculated versus measured annual balance for the 8 North Cascade glaciers with ongoing records for the entire period. That a simple model such as this provides reasonable results indicates the close connection between the regional climate conditions and the mean annual balance of North Cascade glaciers.

5 Mass balance forecasting from climate indices

A number of papers have examined the relationship of Pacific Northwest glacier mass balance to atmospheric circulation indices (McCabe and Fountain, 1995; Hodge et al., 1998; Bitz and Battisti, 1999; Pelto and Miller, 2003). They have shown that these glaciers correlate with the Pacific Decadal Oscillation (PDO) and Multivariate El Niño Southern Oscillation Index (ENSO) particularly over a multi year period (McCabe and Fountain, 1995; Bitz and Battisti 1999; Hodge et al., 1998). Variations in the PDO and ENSO accounted for 42% and 20% of the variance in annual mass balance respectively of South Cascade Glacier (Bitz and Battisti, 1999). The variances indicate the importance of each index, yet neither ENSO or PDO are well enough correlated with annual balance to provide any reasonable predictive or forecasting ability (Fig. 8) (Pelto and Miller, 2003). The r^2 value is 0.16 between PDO and b_a and 0.52 between ENSO and b_a for the 1984–2005 period.

The PDO Index is the leading principal component of North Pacific monthly sea surface temperature variability, poleward of 20°N (Mantua et al., 1997). During the positive PDO phase warm weather is favored in the Pacific along the northwest coast and over the Pacific Northwest. During

Fig. 8. Scatter plot for annual values of PDO (Mantua and others, 1997), ENSO (Wolter and Timlin, 1998) for the 1984–2004 period. The poor fit of each index is evident.

the negative phase cool ocean water is found off the north-west coast and cooler temperatures across the Pacific Northwest (Mantua et al., 1997). In the past century: “cool” PDO regimes prevailed from 1890–1924 and again from 1947–1976, while “warm” PDO regimes dominated from 1925–1946 and from 1977 through the present (Mantua et al., 1997). It had been postulated in the late 1990’s that a negative PDO phase may have been beginning, however a PDO continues to be dominantly positive through 2006. (data source: <http://jisao.washington.edu/pdo/PDO.latest>).

The El Niño/Southern Oscillation (ENSO) phenomenon is the most observable of the atmospheric circulation indices that lead to year-to-year climate variability. ENSO positive events (El Niño) herald abnormally warm sea surface temperatures (SST) over the eastern half of the equatorial Pacific. La Niña, is the opposite phenomenon, indicative of abnormally cold SST in the eastern half of the equatorial Pacific. ENSO is an east-west atmospheric pressure see-saw that directly affects tropical weather around the globe and indirectly impacts a much larger area (Wolter and Timlin, 1998). The ENSO multivariate index used here is based on the principal observed climate variables over the tropical Pacific. The index is a weighted average of the main ENSO features contained in the following six variables: sea-level pressure, the east-west and north-south components of the surface wind, SST, surface air temperature, and total amount of cloudiness (Wolter and Timlin, 1998)(data source <http://www.cdc.noaa.gov/people/klaus.wolter/MEI/table.html>). Sustained positive values of this ENSO index often indicate El Niño episodes. These positive values are usually accompanied by sustained warming of the central and eastern tropical Pacific Ocean. Negative values of this ENSO index are associated with stronger Pacific trade winds and warmer sea temperatures to the north of Australia (Wolter and Timlin, 1998).

The positive phase spatial patterns are very similar for both indices and it is postulated that they reinforce each other substantially when in phase (Gershunov et al., 1999).

Table 4. The columns are respectively: Mean value of winter PDOW (October–April). Winter ENSOW (October–April). Glacier net balance b_n –SC from South Cascade Glacier 1960–2005. Glacier annual balance b_a –NC for the 10 NCGCP glaciers (1984–2006). The relative phase: positive, >0.2 (p), negative, <-0.2 (n) and equilibrium -0.2 to 0.2 for equilibrium (e), for PDOW, ENSOW indices and glacier net balance and annual balance (bn-ba) respectively. The number of the rule utilized from Sect. 5. Lastly if the rule correctly yields the annual balance in terms of negative, equilibrium or positive it is noted by a yes, if not a no for both bn-ba. The rule is correct in 41 of 46 years for the South Cascade Glacier for which the model was designed. The rule is correct in 20 of 23 years for the North Cascade Glacier Climate Project glaciers.

Both indices favor anomalously warm sea surface temperatures near the equator and along the coast of North America, and anomalously cool sea surface temperatures in the central North Pacific (Mantua et al., 1997; Gershunov et al., 1999).

Correlation of annual balance and PDO and ENSO atmospheric circulation indices was used to determine the utility for forecasting glacier mass balance from the PDO and ENSO (Pelto and Miller, 2003). Mass balance records from South Cascade Glacier (Krimmel, 2000; Bidlake et al., 2007) and NCGCP glaciers were utilized separately. The goal was forecasting mass balance as early as possible during the hydrologic year. Thus, various combinations of months were used. The best fit was for October–April for both indices. This allows forecasting in May. Table 4 displays the b_n balance of South Cascade Glacier, the mean b_a of NCGCP monitored glaciers, and the October–April mean index values. Each index is a critical indicator for annual balance that when taken alone does not predict specific annual balance values reliably (Fig. 8), but when considered together do provide an assessment of whether mass balance will be positive or negative. In much the same way that the seasonal forecast for the number of hurricanes is determined from a suite of indicators, this seems to be the most reasonable approach for glacier mass balance forecasting. Six forecasting rules are developed that can be applied to 47 possible years 1960–2006 examined. Rule 3 and Rule 4 differ for NCGCP glaciers and South Cascade Glacier. The forecast rules provide a correct assessment in 41 of the 46 years for South Cascade Glacier and 20 of 23 years for NCGCP glaciers.

Rule 1. If both PDO and ENSO are positive, than glacier mass balance will be negative on South Cascade Glacier. This rule works in all 14 of the 14 years. Same for NCGCP glaciers the rule is correct in 8 of nine years.

Rule 2. If PDO is negative and ENSO is equilibrium or negative, mass balance will be equilibrium or positive on South Cascade Glacier. This rule is successful in 13 of 16 years. Same for NCGCP glaciers, and is successful in 9 of 10 years.

Rule 3. If PDO is positive and ENSO is neutral the glaciers will have an equilibrium or negative balance on South Cascade Glacier. The rule is correct in 6 of 7 years. For NCGCP glaciers the result is positive glacier balance, and is successful in 4 of 6 years.

Rule 4. If PDO is negative and ENSO is positive the glacier balance will be negative on South Cascade Glacier. This is true in 5 of 6 years. For NCGCP glaciers the result is positive glacier balance, and is successful in 1 of 1 years.

Rule 5. If PDO is positive and ENSO is negative glacier mass balance will be negative on South Cascade Glacier. This rule provides an accurate result in 2 of 2 years. Same for NCGCP glaciers, and is successful in 2 of 2 years.

Rule 6. If PDO is neutral then glacier annual balance will be negative on South Cascade Glacier. This rule is accurate in 3 of 3 years. Same for NCGCP glaciers, and is successful in 2 of 2 years.

The rule is correct in 41 of 46 years for the South Cascade Glacier. The rule is correct in 20 of 23 years for the North Cascade Glacier Climate Project glaciers. These rules provide us with the capability to forecast glacier annual balance given winter PDO and ENSO values. Given the neutral nature of the PDO and a positive ENSO value in the winter of 2007, it is forecast as of 1 May that North Cascade glacier annual balance will be negative in 2007.

6 Conclusions

Data from the USGS, and NCGCP glacier monitoring programs both indicate that the long-term trend for North Cascade glaciers continues to be strongly negative, despite a slightly positive trend for most glaciers from 1996–2000 (Fig. 3). The consistently high correlation coefficients between glaciers demonstrate the glaciers are responding to a regional climate change. There are no distinct regional variations within the range. The glaciers are in disequilibrium with the present climate as indicated by the mean annual balance loss of -0.54 m/a, a cumulative loss of -12.38 m, 20–40% of their entire volume and increasing negative balances despite retreat (Pelto, 2006)

The combined mean annual balance of the ten glaciers can be reliably calculated using ablation season temperatures from Diablo Dam and 1 April SWE from SNOTEL stations. If the annual balance is calculated for individual glaciers the error increases appreciably. This indicates the strong connection between regional climate conditions and each glaciers annual balance.

Though the statistical and graphical relationship between annual balance and the PDO and ENSO climate indices is not quantitatively strong, both are a key influence of annual balance (Table 4). This is demonstrated being able to correctly forecast the sign of annual balance in 42 of 47 years simply by applying six forecasting rules using October–April PDO and ENSO index values. As predictors of glacier mass balance positive MEI values, El Nino, and warm phase PDO's favor negative balances, and cool phase PDO's and negative MEI values, La Nina, favor positive annual balances.
